Combating the Surge in Fraudulent Job Advertisements: An Evaluation of Machine **Learning Strategies on Data Balancing Techniques**

DOBALLAH Mehdi (mehdo971)

Linköpings Universitet TDDE16 Mehdo 971@student.liu.se Link to the code

Abstract

The number of fraudulent job ads postings has significantly increased in recent years. This activity can be motivated by various reasons such as collecting data to sell it, infiltrating companies for phishing, ransomware, or personal benefits. Several machine learning approaches have been attempted to classify ads for fake jobs. In our project, we are facing a problem: all the public datasets for this kind of research are imbalanced. Therefore, it will be imperative for us to use balancing systems (undersampling/oversampling) to see if they have a positive or negative effect on the model's performance. The performance of the models will be judged based on the AUC score, known for its precision in classifying binary problems.

Introduction

21 Data privacy today is more crucial than ever, 22 especially when it comes to the security of personal 23 information. Countless malicious individuals try 24 their best to make money by selling this information 25 to the highest bidder. One way to collect such 26 sensitive information is by posting fake job ads. In 27 this way, with the increase in the number of job 28 seekers, they massively gather information to later 29 sell. By creating fake job ads, it becomes clear which 30 audience can be targeted, thus potentially causing 31 even more damage with phishing for example

33 With the goal of combating the rising problem of 70 34 fake job ads, researchers worldwide have attempted 71 This method of text vectorization enables machine 35 to develop machine learning models to distinguish 72 learning algorithms to effectively work with textual data

37 main issue encountered in developing such models 38 is that the available datasets are extremely 39 imbalanced, with real job postings far outnumbering 40 the fraudulent ones. This imbalance leads to models 41 being more biased towards the majority class, in this 42 case, genuine job opportunities. In this paper, we explore whether different 43 aim 44 oversampling/undersampling methods can improve 45 the performance of a fraudulent job ad classifier.

Theory

1.1 Count Vectorizer

Machine learning algorithms inherently lack the 49 capability to directly interpret text in its raw form. This necessitates the transformation of text into a format that these algorithms can process and analyze. The process involves vectorizing the text, where each word, or "token", is converted into a numerical representation. This conversion is typically carried out through two main steps: the fitting phase and the transform phase.

During the fitting phase, the algorithm scans a 58 collection of documents to identify and assign a unique 59 numerical index to every distinct token it encounters. 60 This step essentially builds a vocabulary of all unique 61 words found across the documents.

Subsequently, in the transform phase, each document 64 is converted into a sparse matrix based on this 65 vocabulary. In this matrix, rows represent individual 66 documents, and columns correspond to the unique 67 tokens identified during the fitting phase. The entries in 68 this matrix indicate the frequency of each token within 69 each document.

36 between real and fraudulent job advertisements. The 73 by quantifying the presence and prevalence of words in

74 a manner that's analyzable, allowing for further 130 75 processing and insight extraction from text-based 131 the primary metric for optimizing the decision-making 76 datasets.

1.2.1 Bernoulli Naïve Bayes

79 that all features are conditionally independent, given the 135 incorrectly labeled if it was randomly labeled according 80 target class, which can be either win or loss (here 0 or 1/ 136 to the distribution of labels in the subset. 81 fraudulent or non-fraudulent). The Bernoulli Naive 137 Mathematically, it's defined as Gini(p) = $1 - \sum_{i=1}^{C} p_i^2$, Bayes is a part of this type of classifiers.

84 binary variables, the likelihood of a document given a 140 the most appropriate attribute and its corresponding 85 class Ck can be expressed as $p(X|\mathcal{C}_k) = \prod_{i=1}^n p_{ki}^{x_i} (1-141)$ threshold by minimizing the likelihood of incorrect p_{ki})^(1- x_i), where p_{ki} represents the probability of Class ¹⁴² classifications, thus steering the model training towards 87 Ck generating the term xi.

1.2.2 Logistic regression

The logistic model, a cornerstone in statistical 145 90 analysis, offers a way to predict the likelihood of a 146 for their efficiency in classifying data with high 91 particular event by relating the log odds of the event to 147 dimensionality, which is pertinent to our scenario. The 92 independent variables through a linear relationship. 148 kernel function for Linear SVMs is defined Essentially, it employs a logistic function, encapsulated 149 as $K(x_i, x_j) = x_i^T x_j$, indicating a straightforward linear by the equation $p(x) = \frac{1}{1 + e^{-(\beta_0 + \beta_1 x_1 + \dots + \beta_n x_n)}}$, where x_i 150 relationship between the input vectors. Despite the sentence of the classification problem of the classification problem and p(x) and p(x) are the sentence of the classification problem and p(x) are the sentence of the classification problem and p(x) are the sentence of the classification problem and p(x) are the sentence of the classification problem and p(x) are the sentence of the classification problem. and p(x) symbolize the probability of the event's $\frac{1}{153}$ chosen for its implementation. In a scenario with n97 occurrence, influenced by these variables.

between 0 and 1 (fraudulent and non-fraudulent for us). 157 hyperplane that not only separates the datapoints into 101 The logistic function essentially extends the sigmoid 158 two distinct classes but does so with the maximum 102 function to incorporate multiple independent variables, 159 margin. Essentially, this type of hyperplane divides the maintaining the output's range between 0 and 1, making $\frac{1}{100}$ datapoints labeled as $y_i = 1$ from those labeled as $y_i = -1$ 104 it suitable for estimating probabilities.

Contrary to common perception, logistic regression 162 data point from either category. 106 itself does not categorize outcomes into distinct classes; 163 Mathematically, the equation of any hyperplane can be 107 instead, it calculates the probability of an event. 164 expressed through the set of points x that fulfill the 108 Classification is achieved by setting a threshold: 165 equation $w^Tx - b = 0$, where w is a weight vector 109 probabilities above this cutoff are assigned to one class, 166 perpendicular to the hyperplane, and b is the bias term 110 and those below to another. This binary classification 167 that provides the displacement of the hyperplane from 111 mechanism enables its application in various fields, 168 the origin. The objective is to optimize w and b such at 112 from medicine to ML, where it's crucial to predict 169 the margin, or the distance between the hyperplane and categorical outcomes based on a set of predictors.

1.2.3 Decision Trees

Decision trees has a structure composed of numerous 172 116 internal decision-making nodes. These nodes evaluates 173 117 specific attributes to guide decisions (for instance, 174 118 assessing cloudiness to predict rain). Each pathway 175 119 emanating from a node symbolize a potential outcome 176 designed to address imbalances in the class distribution 120 based on the attribute evaluation. The tree's terminal 177 of a dataset. Their aim is to create a more balanced class 121 nodes, known as leaf nodes, conclude the decision 178 distribution, thereby enhancing the performance of making process. The journey from the root node to any 179 machine learning models that may struggle with skewed leaf node delineates a set of rules for classification. At 180 datasets. 124 every node, decisions are made based on whether a 181 125 feature's value meets a certain criterion, typically 182 number of instances in the minority class(es). This can formulated as $x_i \le threshold$, where x_i represents the 183 be achieved through various methods, such as simply 127 attribute's value at node i, and the threshold is a 184 duplicating existing minority class samples or by 128 predetermined constant derived during the model's 185 generating new samples that are similar to the existing 129 training phase.

This study focuses on employing the Gini impurity as 132 process at each node. The Gini impurity is a measure 133 designed to evaluate the frequency at which any Naïve Bayes classifiers operate under the assumption 134 randomly chosen element from the set would be where p_i denotes the proportion of elements belonging If we denote by x_i the i-th binary variable out of n 139 to class i within the node. This metric aids in selecting

1.2.4 Support Vector Machines

Support Vector Machines (SVM) are highly regarded occurrence, influenced by these variables.

Central to this model is the sigmoid function, $\sigma(t) = \frac{1}{1+e^{-t}}$, which ensures output values are constrained to the sigmoid function, $\sigma(t) = \frac{1}{1+e^{-t}}$, which ensures output values are constrained to the sigmoid function, $\sigma(t) = \frac{1}{1+e^{-t}}$, which ensures output values are constrained to the sigmoid function, $\sigma(t) = \frac{1}{1+e^{-t}}$, which ensures output values are constrained to the sigmoid function, $\sigma(t) = \frac{1}{1+e^{-t}}$, which ensures output values are constrained to the sigmoid function, $\sigma(t) = \frac{1}{1+e^{-t}}$, which ensures output values are constrained to the sigmoid function, $\sigma(t) = \frac{1}{1+e^{-t}}$, which ensures output values are constrained to the sigmoid function, $\sigma(t) = \frac{1}{1+e^{-t}}$, which ensures output values are constrained to the sigmoid function, $\sigma(t) = \frac{1}{1+e^{-t}}$, which ensures output values are constrained to the sigmoid function, $\sigma(t) = \frac{1}{1+e^{-t}}$, which ensures output values are constrained to the sigmoid function $\sigma(t) = \frac{1}{1+e^{-t}}$. 161 1, ensuring the greatest possible distance to the closest

> 170 the nearest points from both classes, is maximized, thereby enhancing the classifier's discriminative power.

1.3 Oversampling/Undersampling methods

Oversampling and undersampling are strategies

Oversampling techniques work by increasing the 186 ones using algorithms like Synthetic Minority Over188 sampling (adasyn). The goal is to elevate the minority 244 generated. 189 class to a level where it holds a more comparable 245 190 representation relative to the majority class, thus 246 191 reducing bias towards the majority class.

193 number of instances in the majority class(es). This could 249 neighbors method to measure the similarity between 194 mean randomly removing samples from the majority 250 data points, specifically aiming to identify and eliminate 195 class to decrease its size and bring the class distribution 251 those majority class samples that are closest to the 196 closer to equilibrium (Near Miss). While effective in 252 minority class samples. 197 balancing the dataset, this approach risks losing 253 198 potentially valuable information contained within the 254 sample, the algorithm finds it's k-nearst neighbors 199 majority class samples that are discarded.

1.3.1 SMOTE

201

203 Technique, is a method used to generate new samples in 259 majority class samples that are nearest (i.e., most 204 the feature space to address the problem of class 260 similar) to the minority class, based on the rationale that 205 imbalance in machine learning datasets. It operates 261 these are less critical for defining the boundary between within a dataset that comprises n samples, each with m 262 the classes. By removing the samples with the smallest 207 features.

211 space; typically, k = 5 is chosen. The creation of a 267 better classification performance. 212 synthetic data point then follows this initial step.

214 of the k neighbors and constructs a vector from the 270 selecting which majority class samples to remove. The 215 chosen neighbor to the original sample. This vector is 271 version detailed here is known as Near-Miss Version 1. 216 then multiplied by a random number x, which ranges 272 This version specifically focuses on minimizing the 217 between 0 and 1, effectively determining how far along 273 presence of majority class samples that are closely 218 the vector the synthetic point will be placed. Adding this 274 resembling the minority class, thereby attempting to 219 scaled vector to the original sample point results in the 275 simplify the task of distinguishing between the two 220 creation of a new, synthetic data point within the feature 276 classes for a classification algorithm. 221 space, thereby augmenting the minority class with 277 222 artificially generated, yet plausible, samples. This 278 223 technique helps in balancing the class distribution, 279 Curve Score 224 enhancing the performance of machine learning models 280 225 on imbalanced datasets.

1.3.2 Adaptive synthetic sampling

228 different groups within the minority class based on their 284 graphical representation that plots the true positive rate 229 level of learning difficulty. The more challenging the 285 (TPR) against the false positive rate (FPR) at various 230 data is to learn, the higher the number of synthetic data 286 threshold settings. It demonstrates the trade-off between 231 generated. This approach enhances learning compared 287 sensitivity (or TPR) and specificity (1 - FPR) across 232 to data distributions in two ways: it reduces bias 288 different thresholds without committing to a particular 233 introduced by class imbalance and adaptively shifts the 289 classification cut-off. 234 classification boundary with respect to data with 290 235 insufficient representation." (Méthode de rééquilibrage 291 236 des classes en classification supervisée, Merwan 292 negatives correctly would have an ROC curve that rises 237 CHELOUAH). The ADASYN algorithm, a variation of 293 vertically up the y-axis and then moves horizontally 239 instead of linear correlations. It uses the density of 295 indicating perfect performance. Conversely, a model 240 observations, generating more data in areas where the 296 with no discriminative power, equivalent to random density of sub-effects is lower. This density is calculated 297 guessing, would produce a diagonal line from the

187 sampling Technique (SMOTE) and adaptive synthetic 243 class around the point where new synthetic samples are

1.3.3 Near-Miss

The Near-Miss algorithm is an undersampling technique designed to help balance datasets by reducing Conversely, undersampling involves reducing the 248 the size of the majority class. It employs the k-nearest

In the process described, for each majority class 255 wihtihn the minority class, with k typically set in this 256 paper. It then calculates the aggregate distance from the 257 majority class sample to these k-nearest minority class SMOTE, or Synthetic Minority Oversampling 258 neighbors. The key idea is to prioritize the removal of 263 total distance to the minority class, the algorithm The process begins by selecting a random sample 264 effectively retains those majority class samples that are from the minority class. For this chosen sample, 265 most dissimilar from the minority class, aiming to SMOTE identifies its k nearest neighbors in the feature 266 preserve the integrity of the class boundary and facilitate

It's important to note that there are three versions of To generates this new datapoint, SMOTE selects one 269 the Near-Miss algorithm, each with its own approach to

1.4 Receiver Operating Characteristic and

The Receiver Operating Characteristic (ROC) curve 281 and the Area Under the Curve (AUC) score are crucial 282 metrics for evaluating the performance of models in "The main idea is to use a weighted distribution for 283 binary classification problems. The ROC curve is a

A model that perfectly predicts all positives and SMOTE, takes into account variance between points 294 along the x-axis, essentially forming a right angle and based on the number of observations from the majority 298 bottom left corner to the top right corner of the ROC 299 space.

The AUC score quantifies the entire two-dimensional 302 area underneath the entire ROC curve from (0,0) to 303 (1,1). This score provides a single scalar value that 304 summarizes the model's performance across all 305 threshold values, making it easier to compare different 306 models. A higher AUC value indicates better model 307 performance, with a score of 1.0 representing a perfect 308 model and a score of 0.5 indicating a model that 309 performs no better than random chance. The AUC score 310 is particularly useful because it is independent of the 311 classification threshold and provides an aggregated performance 312 measure of across possible 313 classification thresholds.

314 2. Data (dataset Here)

300

342

This project dives into a dataset found on Kaggle,. It is a CSV file with 18 kinds of information. Our focus is mainly oriented on the job description if they're marked as fraudulent (Figure 1), if they have a logo (Figure 2), if experience is required (Figure 3), the employment type (Figure 4) and the required education (Figure 5). These precise data give us a lot to work with for spotting fake job ads.

One big challenge we notices is that the dataset is

To better understand and work with the dataset, we cleaned up the text by lemmatizing: which simplifies words to their base format, and removing stop words: which don't add much meaning in the classification. We did this cleanup separately for the real and fake job ads in order to have a point of view well-marked on both side.

Below we have a realistic look on how the data is distributed between fraudulent and non-fraudulent and interesting values.

Figure 6: AUC Score

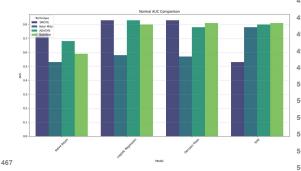

Figure 7: Comparison Normal Score AUC

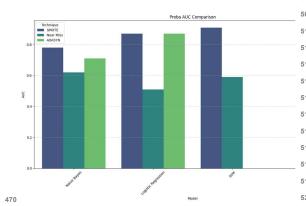

Figure 8 : Comparison Probabilistic Score AUC

Conversely, the performance metrics for other 476 algorithms remained relatively stable across the 477 baseline, SMOTE, and ADASYN interventions. These models demonstrated robust initial performances, with AUC scores consistently near 480 0.80, experiencing only slight improvements with 481 SMOTE except with SVM model. When using 482 SMOTE, the synthetic samples created for the 483 minority class could be introducing noise or they 484 might not represent the true underlying distribution 485 accurately, leading to a more complex decision 486 boundary that an SVM struggles to learn. This is 487 where ADASYN is better. However, we notice a 488 remarkable decrease for Near-Miss algorithm. 489 Near Miss focuses on the points closest to the 490 decision boundary, which might result in a biased 491 sample that does not represent the true distribution 492 of the majority class. Such significant information 493 loss can adversely affect the model's performance, 494 especially in complex models that rely on capturing 495 intricate patterns in the data which is our case here (Figure 5)

Incorporating a probabilistic perspective into 499 our analysis provides additional depth to our 500 understanding of model performances. This 501 approach allows us to evaluate not only the 502 accuracy of the models' predictions but also the 503 confidence levels associated with these predictions. 504 The significant response of the Naive Bayes 505 algorithm to data balancing techniques, as 506 observed through probabilistic measures. 507 underscores the importance of considering model 508 certainty. This probabilistic analysis offers valuable 509 insights into the dynamics between model 510 performance and data preparation techniques, 511 highlighting the nuanced benefits of employing 512 probabilities in the evaluation of machine learning 513 algorithms.

According to Figure 8 reflecting on the Proba 515 AUC values, we observe a compelling trend where models applying probabilistic methods demonstrate superior performance across all techniques, compared to their Normal AUC counterparts. This phenomenon is particularly 520 notable with the ADASYN technique, where we 521 see enhancements in the AUC scores for all 522 models. For instance, the Naive Bayes model ₅₂₃ exhibits a climb from a Normal AUC of 0.68 to a 524 Proba AUC of 0.71, and the Logistic Regression model ascends from 0.83 to 0.87 when employing 526 probabilistic scoring. The Decision Trees model

527 follows suit with an increase from 0.78 to 0.87. 577 of machine learning models to achieve a more 528 However, it's important to note that the Proba AUC 578 refined and dependable analysis. 529 value for the SVM model is not available (due to 579 530 computing power), hence we cannot comment on 580 531 the probabilistic improvement for this particular 581 of constraints. A notable limitation was our reliance 532 model under the ADASYN technique.

534 These findings underline the value of using 584 tuning. This approach may have capped our ability 535 probabilistic models, especially when dealing with 585 to achieve and explore the full potential of the 536 imbalanced datasets treated with oversampling 586 algorithms and the balancing techniques. Future 537 methods such as ADASYN, emphasizing the 587 studies could greatly benefit from auto-tuning 538 potential of probabilistic approaches in enhancing 588 across all algorithms, potentially unveiling 539 the model's ability to differentiate between classes 589 optimized performance nuances. 540 more effectively. In addition, it helps to put aside 590 other method like Near-Miss coupled with SVM 591 542 algorithm: The AUC score is relatively low and the 592 incorporating a wider array of machine learning 543 likelihood is not very consistent which provide a 593 models, particularly those adept at handling both 10w confidence.

546 5. Discussion

545

548 class balancing techniques, such as oversampling 599 preprocessing phase could further refine the data and undersampling, on the efficacy of machine 600 quality, potentially leading to more accurate 550 learning algorithms in identifying fraudulent job 601 classification outcomes. advertisements. Our research unveiled that, generally, the influence of these techniques on the 602 6. Conclusion and future work 553 algorithms tested did not markedly alter their 603 554 performance, with the notable exception of the 604 preprocessing raw text to make it understandable 555 Naive Bayes classifier. This anomaly with Naive 605 for machine learning algorithms. This process 556 Bayes suggests an area ripe for further 606 entailed removing stopwords, words that do not 557 investigation in upcoming studies.

560 integration of a probabilistic approach to our 610 its base or dictionary form. This foundational step 561 analysis. This method allowed us to not only 611 is crucial for clearing the noise in the data and 562 predict classifications but also to understand the 612 ensuring that the algorithms can focus on the 563 confidence levels behind these predictions. 613 meaningful content within the text. Employing probabilistic view offers a deeper layer 614 When we applied traditional machine learning 565 of insight, providing clarity on how certain the 615 methods without hyperparameter tuning to our 566 model is about its predictions, especially in 616 data, we observed that the performance, as 567 complex scenarios like fraudulent job ad detection. 617 measured by the AUC score, remained relatively 568 This aspect of our research underscores the 618 unchanged across different class balancing 569 potential of probabilistic analysis in enhancing 619 techniques, with the exception of the Naive Bayes interpretability and reliability. 571 probabilistic approach offers a 572 understanding of model certainty, which could be 622 and ADASYN techniques, as evidenced in the ₅₇₃ instrumental in domains where the cost of ₆₂₃ results table (Figure 6) This distinct behavior of 574 misclassification is high. Consequently, the 624 the Naive Bayes classifier compared to other 575 findings reinforce the argument for incorporating 625 algorithms raises intriguing questions for future

Nonetheless, our investigation comes with its set 582 on default hyperparameters as specified by the 583 utilized Python libraries, without engaging in auto-

Furthermore, our study could be expanded by 594 textual and numerical data. Given that our dataset 595 encompasses numerous numerical attributes, such 596 as required experience levels, leveraging models 597 that can process this multifaceted data might yield In our exploration, we delved into the effects of 598 more nuanced insights. Additionally, advancing the

A pivotal aspect of text mining involves 607 contribute significant meaning to the text, and any 608 non-alphabetical characters. Subsequently, each A significant addition to our study was the 609 word was lemmatized, meaning it was converted to

The 620 classifier. This classifier showed a notable nuanced 621 improvement, particularly with the use of SMOTE 576 probabilistic measures into the evaluation metrics 626 research. Understanding why Naive Bayes benefits 627 more significantly from class imbalance handling 628 could provide valuable insights into its mechanics 676 Feng Li and al. (2020) A Novel Simplified 629 and potential optimizations.

These findings highlight the importance of 678 631 selecting appropriate preprocessing techniques 679 632 tailored to the specific dataset and problem domain. 680 Merwan 633 Moreover, the integration of probabilistic analysi, 681 634 emphasizing its utility in enhancing the robustness 682 635 and reliability of binary classification tasks, 683 Haibo He, Yang Bai, Edwardo A. Garcia, and Shutao 636 especially in complex and ambiguous contexts like 684 job detection. 637 fraudulent ad Therefore, 685 638 incorporating both class balancing techniques and 686 639 probabilistic measures can significantly enhance 687 640 the effectiveness of machine learning models, 641 ultimately contributing to more accurate and 689 Marcel Bollman, TDDE16 642 dependable analyses.

Moreover, a substantial challenge in this field is 693 the acquisition of a robust dataset of fraudulent job 694 Future Internet, 9(1). 646 ads. The scarcity of verified fraudulent ads 695 Wikipedia : Bag of words, Baseline, Bernoulli 647 complicates the task of building a comprehensive 696 Naïve Bayes, Decision Trees, Support vector and reliable dataset. The uncertainty surrounding 697 machine, Logistic Regression, Smote, the authenticity of collected ads adds another laver 698 Receiver operating characteristics 650 of difficulty, highlighting the need for meticulous 651 verification processes and the exploration of novel collection strategies. 652 data This challenge 653 underscores the ongoing struggle in leveraging 654 machine learning for fraud detection, emphasizing 655 the importance of quality data in developing 656 effective and accurate predictive models.

658 Acknowledgments

643

I would like to express my profound 660 appreciation to Professor Gerald Forhan for 661 guiding me towards this research topic. His 662 direction was particularly invaluable at a time when I was struggling to find substantial depth in 664 my previous subject. Professor Forhan's insights and guidance not only clarified my path but also made it possible for me to delve deeply into an area that perfectly aligns with my interests.
